(54) Title: **PROCESS AND DEVICE FOR DISPENSING POLYURETHANE FOAMING MATERIAL**

(57) Abstract: Chemically reactive liquid components, comprising a polyol (A) and an isocyanate (B), are mixed with a CO₂ blowing agent, into a mixer (14) at a pressure sufficient for maintaining the CO₂ dissolved into the liquid mixture. The resulting liquid mixture is subsequently fed to a foam dispensing device (10), making the mixture to flow along a restricted flow-path (16; 24) comprising a pressure-drop slot (16A; 24A) which extends in the direction of the flow and is dimensioned to provide a back-pressure in the upstream mixture to maintain CO₂ in a dissolved state. The pressure in the mixture is gradually reduced while it is flowing at laminar condition along the pressure-drop slot (16A; 24A), while nucleation and frothing are performed by generation turbulency and eddies in the mixture which is flowing along an exit portion (16B, 16C; 16D; 16E; 24B, 24C) of the path (16; 24) consisting of an extension of the pressure drop slot (16A; 24A).

WO 01/10623 A1

PROCESS AND DEVICE FOR DISPENSING POLYURETHANE FOAMING MATERIAL

BACKGROUND TO THE INVENTION

5

The present invention relates to the production of polyurethane foams either of flexible or rigid type from a chemically reactive liquid mixture comprising a polyol and an isocyanate, which are pre-expanded or frothed by an inert low boiling blowing agent highly soluble under pressure in the polyurethane forming mixture, such as carbon dioxide (CO₂). More particularly the invention relates to a process and to a device for dispensing a polyurethane foaming material in the continuous production of polyurethane foam slab stocks.

In the production of polyurethane foams, both of the flexible and rigid type, various methods and devices have been proposed, including the use of the known "frothing" or pre-expansion technology, whereby a low-boiling non-reactive blowing agent, in particular carbon dioxide (CO₂), is dissolved under pressure in the polyurethane forming mixture hereinafter also referred to as polyurethane mixture, or in one of its chemical components, at a pressure equal to or higher the equilibrium pressure, for example at a pressure ranging between 5 and 20 Atm to maintain the CO₂ dissolved in the liquid mixture until feeding to a dispensing device where frothing take place.

The use of carbon dioxide added to the chemical formulation, as a blowing agent in the production of polyurethane foams, has for a long time been proposed in numerous prior documents, for example in US-A-3.184.419 (MERRIMAN) of 1965 and EP-A-089796 (ICI) of 1982, and suggested in order to avoid certain problems of an

environmental and economic nature which occurred with conventional blowing agents, such as fluorocarbons or chlorofluorocarbons, however this previous suggestions failed to provide a process and a dispensing device
5 suitable for industrial scale applications.

In the production of polyurethane foams pre-expanded by CO₂, technical problems also arose which were found to be difficult to solve. In particular, during the dispensing or
10 laying down of the mixture, it was difficult to achieve an adequate control in the reducing of the pressure, and a gradual release of the CO₂ in the frothing polyurethane mixture. The foam generally had numerous defects, such as cavities or large holes, and an irregular cellular
15 structure which made the foam produced unacceptable from the commercial viewpoint.

In order to find an industrially effective solution to this awkward problem, EP-A 0 645 226 proposed a special
20 dispensing device whereby it is possible to distribute, in a controlled manner, a frothing polyurethane mixture, while it is distributed on a substrate.

In particular, in EP-A-0 645 226 the use of a lay down
25 device for dispensing a foaming polyurethane material, has been proposed for dispensing a liquid polyurethane mixture containing a certain percentage of carbon dioxide (CO₂) and nucleation gas, in which the CO₂ has previously been dissolved under pressure in one of the chemical components,
30 or in the same mixture, at a critical pressure for example between 5 and 20 bar, sufficient for maintaining the carbon dioxide dissolved in the liquid mixture allowing to initiate frothing under pressure controlled conditions to avoid turbulent evaporation of CO₂ upon discharge of the
35 same mixture from pressure drop-zone.

This device substantially comprises a pressure equalising chamber and a pressure drop zone which opens towards a frothing cavity. The pressure drop zone is defined by an elongated slot of restricted height, provided by smooth walls which extend in the flow direction of the mixture, or by a plurality of holes. By means of a such pressure drop zone, it is possible to achieve a gradual pressure reduction in the laminar flow of the liquid mixture and a controlled release of the CO₂ in gaseous form downstream the outlet of the pressure drop slot in an enlarged frothing cavity provided for distribution of the froth.

Devices of this type have in practice shown to operate in an appropriate manner and allow the production of pre-expanded foams of good quality, having a regular cellular structure, substantially free from large bubbles or cavities.

Nevertheless, in order to achieve a good start of the frothing, it is necessary to introduce into the liquid polyurethane mixture a quantity of non-soluble nucleation gas, for example nitrogen or air in a large amount of 70-90 litres/min., depending on the flow rate, which has to be appropriately dispersed into the liquid mixture to form finely divided gaseous "nuclei" around which the microscopic bubbles of CO₂ released into the mixture aggregate, to cause frothing.

The use of nucleation gas nevertheless entails other problems which may be partially solved by a compromise between quantity of nucleation gas dispersed into the polyurethane mixture, and quality or properties of the polyurethane foam.

Furthermore an excess of nucleation gas can lead to an uncontrollable frothing, with violent release of the CO₂ into the mixture and consequent formation of an irregular cellular structure. Therefore, in the production of expanded polyurethane foams an excess or lack of nucleation gas may lead to defects in cell formation, i.e. to the formation of an irregular and uneven cell structure with creation of large bubbles and cavities. With traditional process and dispensing devices it is therefore difficult to control, in the time and in the width of the dispensing device, to the correct extent the quantity of nucleation air dispersed in the liquid polyurethane mixture.

There is therefore the need to improve this technology further, at the same time making it suitable for many applications.

OBJECTS OF THE INVENTION

The main object of the present invention is to provide a process and a foam dispensing device for the production of both flexible and rigid polyurethane foams from a polyurethane mixture pre-expanded by means of the frothing technique, such as to avoid the disadvantages of the previously referred devices.

More particularly an object of the present invention is to provide a process for the production of a polyurethane foam by frothing a polyurethane liquid mixture containing carbon dioxide (CO₂) as blowing agent, such as to avoid the use or allow a substantial reduction in the content of nucleation gas dispersed in the liquid mixture, in this way avoiding the problems of defective cell formation.

A further object of the present invention is to provide a

process as referred to above, which also allows an adequate control of the frothing step and quality of the foam.

Yet another object of the invention is to provide an apparatus for performing the process referred above, which has a simplified construction, and which allows a control of the nucleation and frothing steps, acting at a microscopic level directly on the fluid threads which flow along an elongated and restricted path or slot of a pressure drop zone, unlike apparatus of the type previously known, where the control takes place within considerably larger dimensions, in a frothing cavity provided at the exit end of the pressure drop zone, as shown for example in the prior EP-A-0 645 226 in which frothing occurs after the kinetic energy of the flow exiting the slot has been almost totally dampened, as shown in Figure 9 of the accompanying drawings.

Lastly, another object of the present invention is to provide a process and a dispensing device for the production of a frothed polyurethane foam, suitable for the continuous manufacture of polyurethane foam slab stocks.

BRIEF DESCRIPTION OF THE INVENTION

According to a general aspect of the invention, a process has been provided for the production of polyurethane foams comprising the steps of:

- mixing at least a first and a second chemically reactive components, such as a polyol and an isocyanate with carbon dioxide under critical pressure condition to maintain the carbon dioxide dissolved into the resulting liquid mixture;
- gradually reducing the pressure into the mixture while it is flowing at laminar condition along a first portion of

a restricted flow path comprising a pressure-drop slot longitudinally extending in the flow direction and dimensioned to provide a back-pressure in the upstream mixture sufficient to maintain the carbon dioxide in a dissolved state,

characterised by the addition step of:

- causing nucleation and frothing of the mixture, by generation localised turbulence and eddies formation to release gaseous carbon dioxide into the mixture while it is flowing along a remaining portion of the restricted flow-path consisting of an extension of the pressure-drop slot.

According to a particular aspect of the invention, the localised turbulence or whirling conditions in the flow of the flowing mixture, close to the exit end of the pressure drop slot, are generated by causing sudden changes in the flow direction of the mixture, around sharpened edges, for example by shaping an end portion of the flow path with one or more successive slots angularly arranged each other, for example with a Z like shape, or by providing a plurality of fine teeth on opposite side walls, to generate one or more repeated flow diversions of the fluid threads and a condition of localised micro vortices or eddies, which in turn generates a diffused nucleation into the liquid mixture, and a gradual release of the gaseous CO₂ into the mixture which flows towards the exit of the flow path, to be fed or delivered onto a substrate or in an underlying zone.

According to another aspect of the invention, a foam dispensing device has been provided for producing a pre-expanded or frothed polyurethane mixture by the process referred to above, which device is in the form of a circular device or of an elongated bar which extends for

example in a cross direction of the flowing mixture or a moving substrate on which the frothing polyurethane material is delivered, for example in the continuous production of polyurethane foams slab stocks, or it can
5 assume other different shapes for a different use.

The foam dispensing device preferably comprises a flow distribution chamber which is fed with a pressurised CO₂-containing liquid polyurethane mixture, a pressure drop
10 zone in the form of a narrow and elongated slot which extends in the flow direction of the mixture, and which comprises a first axially elongated portion for pressure reduction, and an intermediate short frothing portion for the generation of localised eddies directly in the flow of
15 the mixture, close to the exit of the pressure drop slot.

According to another aspect of the invention an apparatus has been provided for the production of foamed polyurethane material from reactive chemical components comprising a
20 polyol and an isocyanate which are mixed with CO₂ at a sufficient pressure for maintaining the CO₂ dissolved in a resultant liquid mixture, said apparatus comprising:

- a mixer device;
- a foamed material dispensing device, connected to the
25 mixer device;

said dispensing device including a distribution chamber for the liquid mixture opening into a flow path which extends in the direction of the flow,

wherein said flow path comprises a first portion in
30 the form of an elongated pressure-drop slot, for gradual reduction of the pressure, and a second portion conformed to cause whirling or eddies formation into the flowing mixture by angular diversions of the flow, and a diffuser connected to the exit side of the flow path.

BRIEF DESCRIPTION OF THE DRAWINGS

These and further features of the invention, and some embodiments thereof, will be described in greater detail hereinbelow with reference to the accompanying drawings, in which:

- Fig. 1 is a perspective view of part of a system for the continuous production of polyurethane foams, designed to illustrate the process and an embodiment of the device according to the invention;
- Fig. 2 is an enlarged cross sectional view of the device of Figure 1;
- Fig. 3 is a greatly enlarged detail of the exit portion of the device of Figure 2;
- Fig. 4 is an enlarged detail of the exit portion, for a second embodiment of the device of figure 1;
- Fig. 5 is an enlarged detail of the exit portion, for a third embodiment;
- Fig. 6 is a cross sectional view of a further embodiment of the foam dispensing device according to the invention;
- Fig. 7 is an enlarged cross sectional view along line 7-7 of Fig. 6, for a first embodiment of the device of figure 6;

- Fig. 10 shows a schematic view of a tested embodiment similar to that of figure 4;
- Fig. 11 shows an enlarged detail of figure 10.

DETAILED DESCRIPTION OF THE INVENTION

The invention will now be described in greater detail with reference to the accompanying drawings, in which some

preferred embodiments are illustrated.

As referred previously, the process and the device according to the present invention are useful for the production of both flexible and rigid foams, of the open or closed cell type, particularly but not exclusively in the continuous production of foam slab stocks.

A polyurethane foam is typically produced by making various chemically reactive liquid components react, such as a polyol, an organic isocyanate and water, together with an emulsifier, a non-soluble nucleation gas, for example air or nitrogen, a catalyst and a blowing agent, the rigid or flexible nature of the foam depending in general on the formulation of the mixture, in a manner in itself known. For the purposes of the present invention, liquid polyurethane components refer to any polyol, any isocyanate (TDI - MDI) or their derivatives, using generally known standard formulations, or specially provided for the production of rigid or flexible polyurethane foams in general.

The present invention starts from the observation, made through several experimental tests, unlike commonly known conventional methods, that it is possible to reduce considerably the content of nucleation gas dispersed in the liquid mixture, and therefore substantially reduce the rising of cell formation defects, at the same time obtaining controlled frothing of the polyurethane mixture, acting directly on the flowing conditions of the mixture before delivery. In particular it has been discovered that the flow conditions can be advantageously modified while the liquid mixture is flowing along a restricted flow path comprising a restricted slot which longitudinally extends in the same flow direction of the mixture, comprising a

pressure-drop slot in which the fluid is running at a substantially laminar flow condition, where most of the pressure in the polyurethane mixture is gradually reduced, substantially without any releasing of CO₂ gas, which
5 extend into a frothing slot or remaining portion of the restricted flow path, for generation of a localised turbulency or whirling conditions, having an extremely reduced length compared to the pressure-drop slot, comparable to pressure-drop slot, or slightly greater, near
10 the exit for the mixture, in which diffused nucleation takes place through a mechanical or hydraulic effect, as well as a gradual release of the CO₂ in gaseous form, to start pre-expansion or generate controlled frothing conditions directly in the flow of the polyurethane mixture
15 while it running along the final portion of the flow path.

With reference to Figures 1 to 4, the process and a first preferred embodiment of the foam dispensing device according to the invention, will now be described in
20 greater detail.

In Figure 1 a schematic view is given of the basic elements of an apparatus for the continuous production of polyurethane foam slab stocks, in a manner per known, for
25 example as described in the earlier EP-A 0 645 226 filed on 11 July 1994 in the name of the Dutch company FOAMING TECHNOLOGIES CARDIO BV, which forms an integral part of the present description.

30 Reference 10 denotes a dispensing device for feeding a frothed polyurethane mixture, in the form of a linear bar which extends transversely for part or for the entire width of a mobile substrate 11, whereon the frothed polyurethane mixture 12 is continuously deposited and made to move
35 forwards at a preset speed along a curing zone for the

continuous formation of slab stocks of expanded foam.

5 The foam dispensing device 10, is connected by means of a conduit 13 to a mixer 14, for example of the low pressure type, wherein the polyurethane components A and B to be mixed are fed together with the various additives and a preset percentage of carbon dioxide previously dissolved in one of the two components, or directly fed into the same mixing device.

10

Owing to the high capacity of the carbon dioxide (CO₂) to make a liquid in solution with the chemical components, or with the polyurethane mixture, the content of dissolved CO₂, as a percentage of the total mixture, is in general variable compatibly with the required expansion degree for the polyurethane foam and with the required properties of density for the foam.

15

In general, the amount of CO₂ can be between 1% and 10%, or higher, on the total mixture, while its dissolving can be achieved by injecting it directly into the flow of one of the polyurethane components, as for example denoted by C for the component A, premixing it in a static mixer before definitive mixing with the other components, in the mixer 14.

25

In order to maintain the CO₂ dissolved in the polyurethane mixture without the formation of gas, during mixing it is necessary to work at a pressure equal to or preferably higher than a critical pressure depending on the quantity of CO₂ in the mixture, for example by operating at a pressure between 5 and 20 bar approximately, according to the percentage of dissolved CO₂.

30

35 Similarly, the amount of water used as additional blowing

agent, for the generation of the chemical carbon dioxide required for completing expansion of the foam, can be between 0% and 5% approximately compared to the weight of the reactive mixture, or it can be higher according to the requirements of use.

Similarly, according to an aspect of the present invention, the quantity of nucleation gas dispersed in the reactive liquid mixture, or in one of the components, can be maintained comparatively low, for example 1/10 or 1/5 less than the nucleation gas normally used with conventional methods, at most zero, reducing in this way the risks and disadvantages linked to possible defects of cell formation into the foam.

One preferred embodiment of the dispensing device 10, and its mode of operation according to the invention, will be now described in detail with reference to Figures 2 to 4.

As shown in the enlarged section of Figure 2, the dispensing device 10 substantially comprises two side by side arranged bars 10A and 10B, each including a wide longitudinal groove to conjointly define a tubular chamber 15 connected to the conduit 13 (Fig. 1) for feeding the liquid polyurethane mixture from the mixer 14.

The tubular chamber 15 allows for an equalisation of the pressure and distribution of the liquid mixture, which is fed to a restricted flow path 16 comprising a pressure-drop slot defined by side walls strictly closed together, which develop for the entire length of the chamber 15 and extend in the moving direction of the mixture flowing along the flow path 16.

As shown in Figure 2 and in the enlarged detail of Figure

3, the flow path 16, near the exit 16' for the mixture, is provided with a Z-shaped portion, such as to cause localised turbulency conditions by means of one or more abrupt flow diversions of the mixture while it is running
5 along the slot 16, as explained further on.

As shown in Figures 2 and 3, the flow path 10 comprises first rectilinear portion provided by a slot 16A of comparatively long length, defined by flat walls, wherein
10 laminar flow conditions are established such as to cause a gradual reduction of the pressure in the mixture, equal to or higher than 90% of the existing pressure in the chamber 15. In many cases the pressure drop along the slot portion 16A can be close to or only a few percentage lower the
15 entire pressure difference between the chamber 15 and the open end of the exit 16' of the flow path 16.

Purely by way of an indication, in the production of flexible polyurethane foams, the slot 16A, can have a
20 height S between 0.1 and 0.8 mm, preferably between 0.2 and 0.6 mm, while the total length L1 can indicatively be between 1 and 30 mm approximately, for flow rates Q normally running between 50 and 500 l/min. and with viscosity ρ between 100 and 1000 cps. Preferably, in the
25 case of the example referred above, L1 can be between 15 and 25 mm, even if values higher or lower than those specified above are not excluded, according to the pressure to be generated in the chamber 15, or inside the mixer device 14, and according to the output or flow rate and
30 viscosity of the liquid polyurethane mixture.

The final portion 16' of the flow path 16 consisting of an extension of the slot 16A, is shaped in such a way as to cause the generation of turbulency or whirling conditions
35 suitable for starting intense nucleation and a pre-

expansion or frothing step by a gradual release of CO₂ in gaseous form into the polyurethane mixture while it flows along said final portion 16', as shown in the enlarged detail of Figure 3.

5

As can be seen from this Figure, the lower end of the first rectilinear portion or slot 16A, wherein the mixture runs with a laminar flow, extends in a second portion 16B, also referred to as intermediate portion having an extremely limited length. The intermediate portion 16B is positioned at an angle of 90° in relation to the slot 16A, so as to generate abrupt local flow diversions and consequently the rising of first localised whirling or eddies in the same flow of mixture, followed by a third portion 16C for exit of the mixture, arranged for example parallel to the slot 16A so as to cause, with the intermediate portion 16B, a second abrupt change in the flow of the mixture, and a second generation of localised turbulence or whirling conditions close to the previous one.

20

In the case shown, the three portions 16A, 16B and 16C of the path 16 define a Z-shaped flow path in which the contiguous portions of the slot form an angle of 90° one in relation to the other; however the angle can be greater or smaller than 90°, ranging for example between 70° and 120°, with the intermediate portion 16B slanted towards the final portion 16C in an opposite direction in respect to the flow of mixture running in the slot 16A.

25

As referred previously, the height "S" of the slot can be between 0.1 and 0.8 mm in the portion 16A, preferably between 0.3 and 0.6, and larger in the remaining two portions 16B and 16C. From tests it was noted that, by changing the height S and length of the portions 16A, 16B and 16C of the slot, more generally their reciprocal

35

arrangement and configuration, it is possible to provide a positive influence on the flow state of the mixture and change the properties of the pre-expanded polyurethane mixture at the exit of the dispensing device, in particular the degree of nucleation and the frothing of the same mixture, as well as the properties of the final foamed material.

As a general rule, for the example of figures 2 and 3, the three portions 16A, 16B and 16C of the flow path 16 can have the same height; however it is preferable for the portions 16B and 16C, in which nucleation and the frothing steps of the mixture take place, whose volume tends to increase considerably in relation to the liquid mixture, to have increasing dimensions of the flow path.

Purely by way of an example, denoting by S1, S2 and S3 the height of the path 16 in the sections 16A, 16B and 16C respectively, and denoting by L1 the total length of the path 16, L2 the space between the longitudinal axes of the slot portions 16A and 16C, in Figure 3, that is to say the minimum space between the two flow diversions; likewise denoting by Q the flow rate and ρ the viscosity of the mixture, at fluidinamic conditions, satisfactory results were obtained when these parameters came within the following ranges:

	FLEXIBLE FOAM	RIGID FOAM
S1	0.1 - 0.8 mm	0.1 - 0.5 mm
S2	0.2 - 1 mm	0.1 - 1 mm
S3	0.3 - 2 mm	0.2 - 1.5 mm
L1	1 - 30 mm	1 - 30 mm
L2	0.3 - 1.6 mm	0.3 - 1.6 mm
Q	50 - 500 l/min.	10 - 50 l/min.
ρ	100 - 1000 cps	200 - 2000 cps

In general it is advisable for the space between two successive flow diversions and two successive generation points of localised turbulency, to be such as to prevent the flow from tending to return to a laminar condition, or substantially such.

The general principles of the process according to the invention and the operation of the foam dispensing device shown, are now described in more detail with reference to Figures 2 and 3.

The chemically reactive polyurethane components such as a polyol A and an isocyanate B, in one of which a certain a certain percentage of carbon dioxide has been dissolved, are mixed in the mixing device 14 together with auxiliary components, at a pressure in the mixer 14 sufficient for maintaining the CO₂ dissolved in the liquid mixture. The resulting mixture is then fed to the distribution chamber 15 to be distributed along the entire width of dispensing device 10 and onto an underlying substrate 11, in the form of a frothing material.

More specifically, the polyurethane mixture which is fed into the distribution chamber 15 at a critical pressure equal to or higher than the equilibrium pressure of the CO₂ dissolved in the liquid mixture, at a working temperature close to the ambient, for example at a temperature ranging between 18 and 30°C, flows along the first portion of the flow path 16 provided by a slot 16A where a gradual reduction in the pressure takes place, maintaining a flow of mixture at a substantially laminar condition.

In the slot 16A no nucleation effect therefore occurs, nor any demixing of the CO₂, in that the existing pressure is

still high enough to prevent the development of bubbles of gas in the mixture which flows towards the exit side of the flow path 16.

5 However, near the end of the linear slot portion 16A, where the liquid mixture has a relatively low speed of between 3 and 10 m/sec., calculated on the liquid, i.e. when most of the pressure in the mixture has been approximately reduced by 90-95% of the pressure existing in the distribution
10 chamber 15, due to the greater relative shear between the fluid threads near the walls of the slot, compared to the central part where the shear between fluid threads is considerably less, first micro bubbles generation of gaseous CO₂ start to form along the same walls of the slot,
15 which will enable an intense nucleation effect and frothing of the polyurethane mixture to originate in the successive portions 16B and 16C of the flow path.

20 Starting from this step in which an effect of a differentiate demixing of the gas in the intermediate portion of the slot occurs, a sharp or abrupt change of the flow direction from slot 16A to the intermediate portion 16B is caused, followed by a second sharp or abrupt change of flow direction from the intermediate portion 16B and the
25 final portion 16C.

These sudden changes in direction of the flow create high localised turbulence or whirling which accentuates the demixing of the CO₂ gas in the whole flow of the mixture,
30 in that the pressure is now sufficiently low to allow the development of bubbles of gas.

According to the invention therefore, the first portion of path 16 provided by the slot 16A, generates the pressure
35 drop necessary for allowing the transition of the mixture

from the pressurised zone of the chamber 15 to the final portions 16B, 16C of the path 16, to stabilise the solubility conditions of the CO₂ upstream the dispensing device, maintaining laminar flow conditions. Subsequently, along the final portions 16B, 16C of the path an intense release of micro bubbles of CO₂ occurs both along the peripheral walls and in the entire flow of the mixture due to the localised turbulency or whirling conditions generated by the sudden changes in flow direction, and also due to the increased speed of the same mixture while it is frothing and flowing towards the exit.

In practice, in the intermediate portion 16B of the path 16, an intense nucleation effect occurs with formation of micro bubbles of CO₂ in the entire flow of the mixture, and an incipient pre-expansion or frothing effect take place, which will increase in the final portion 16C as far as the exit of the path 16.

An analysis was performed on the pressure losses in the slot, along the flow path, calculating the specific kinetic energy E_c in the mixture at each slot portion where the change in the direction of flow occurs.

The specific kinetic energy of the liquid at point of the path where a change in direction occurs, is obtained from the following formula:

$$1) E_c = \int_0^{h_0} \frac{1}{2} \rho \frac{V(h)^2}{h_0} dh$$

where

h_0 is the maximum height of the flow path;

ρ the viscosity; and

V(h) the speed of the fluid in the corresponding portions of the flow path.

Having indicated by $k = 0.3$ the coefficient of loss for a change in direction of 90° , the pressure dissipated, and consequently the energy supplied to the mixture at each change in direction, is in turn obtained from the formula:

$$2) \Delta p = k \cdot E_c$$

10

Through several trials performed by changing the dimensions of the portions 16A, 16B and 16C of the flow path 16, within the values referred previously, it was seen that good frothing was achieved when the energy dissipation, or the pressure drop in the final portion of the path 16, at each change of direction, was about between 0.02 and 1 bar, preferably between 0.1 and 0.5 bar, the final frothing effect also depending on the space between two successive changes in direction.

20

Since each change in direction generates a localised turbulency or whirling condition, which would tend to dampen rapidly if it were not adequately maintained, rendering ineffective or substantially reducing the demixing of the CO₂ gas, it was seen that good nucleation conditions and pre-expansion of the mixture were obtained when the length between two successive changes in direction was between h_0 and $3h_0$.

30

The experimental data obtained by the trials have confirmed this hypothesis.

Below and above the values referred previously, the pressure drop at the diversions of flow of the mixture caused pre-expansion or frothing judged not to be good, due

35

to a lack or excess respectively of the supplied kinetic energy.

Figure 4 of the drawings shows a second embodiment for the final section of the flow path 16, designed to cause several changes in direction of the flow and a gradual generation of localised turbulence or eddies according to the present invention.

In the case of Figure 4 a final section 16D of the flow path 16 is provided with a set of fine teeth 17 and 18 on the opposite side walls, for example with teeth having triangular shape, which extend along the entire length of the bar 10.

In the case of Figure 4 the sets of teeth 17 and 18 are opposite one in relation to the other, generating a path formed by a succession of diverging and converging sections designed to create continuous diversions of the flow on both sides, with localised generations of micro turbulence or eddies.

The number of teeth 17, 18 or diverging/converging sections along the toothed portion 16D of the path 16 may vary from case to case; good results were obtained by using a number of teeth or diverging/converging portions between 1 and 5.

Figure 5 of the drawings shows an alternative embodiment as regards the arrangement of the teeth 17 and 18 on the two walls of the end portion of the path 16, compared to the embodiment of Figure 4.

Whereas in the case of Figure 4 the two sets of teeth are opposite each other, in the case of Figure 5 the set of teeth of one wall of the slot is staggered, for example by

half a pitch, in relation to the set of teeth on the opposite wall so as to form a serpentine path 16E which extends in the general direction of the slot portion 16A, such as to provide repeated changes in the flow direction, and a gradual dissipation of energy caused by a sequence of a localised micro turbulency.

In both the cases of Figures 4 and 5 the sets of teeth 17 and 18 have a triangular cross-sectional shape, with an angle at the vertex which can be between 60° and 120° , preferably between 60° and 105° . Moreover the pitch between sets of teeth must be particularly small, of an order of magnitude comparable to the minimum space existing between opposite teeth, for example equal or equivalent to 1+4 times the minimum dimension in height of the same slot or flow path.

Figure 6 schematically shows a further embodiment, particularly suitable for foam dispensing devices of circular shape. In this Figure, reference 20 denotes the hollow body of the dispensing device, having an inlet 21 for the liquid polyurethane mixture which leads into a distribution chamber 22 of conical shape, which widens towards a circular flow path 24 between the outer body 20 and an internal core member 23.

As stated above, between the cylindrical core member 23 and the internal surface of the body 20 a circular path 24 is formed, for example of the type shown in Figure 3, that is comprising a first cylindrical slot 24A which extends in the flow direction of the mixture, coaxially arranged to the same device, an intermediate annular portion 24B arranged in a plane at 90° in relation to the previous one, and a third circular portion 24C at 90° in relation to the previous one, which opens towards the cavity of a diffuser

25.

In the case of Figure 6, as for the case of Figure 3, the slot 24A may also have smooth side walls, shown in Figure 7. Conversely, the first slot portion wherein laminar flow conditions are established, can be formed by a plurality of holes and/or longitudinal grooves 24A', as shown in Figure 8, which again axially extend in the flow direction and which have a length and diameter within the ranges of values referred previously.

In the case of Figure 6, as an alternative to the Z shape in the final section of the path 16, it is possible to use a toothed profile corresponding to that of Figure 4 or 5, or another suitable shape for creating localised turbulence or whirling conditions by sudden changes in the flow direction of the polyurethane mixture, to generate nucleation and frothing by the release of gaseous CO₂ in the same mixture which flows in the final section of the flow path 16.

Figure 9 of the drawings comparatively shows the distribution of the flow of a polyurethane mixture which travels along a narrow slot 26, having an height S1 of 0.25 mm, which leads into a cavity 27 having a front wall 28 at 3 mm from the exit of the slot 26, that is to say of an order of magnitude 12 times greater than the height S1 of the same slot 26.

The graph of Figure 9 was obtained by means of a computer simulation, using the Fluent 4.42 simulation program of FLUENT INC. Figure 9 shows, totally clearly, how the kinetic energy of the flow which leaves the slot 26 is consumed in a very short length about of the order of 1 mm, i.e. equal to 3 or 4 times the height of the slot or

smaller, far from the front wall 28. This simulation confirmed that localised changes in direction of the flow, in accordance with the present invention, must preferably occur when the flow has a sufficiently high state of
5 turbulency.

Lastly figures 10 and 11 show a further embodiment and the result obtained again with numerical computer simulation by 5.3 Fluent program, to study the behaviour of CO₂ dissolved
10 into a polyurethane mixture and the detaching of the fluid threads from the inner wall of a diverging diffuser at the changing of the angle width.

More precisely figure 10 shows a particular shape of the
15 flow path 16 and the diverging diffuser 29; in figures 10 and 11 the same reference numbers of figure 4 have been used to indicate similar or equivalent parts.

As shown in figure 10, the device comprises a slot 16A
20 having an height S1 of 0.3 mm, and a length L3 of 20 mm, an intermediate toothed portion 16D, and a final portion 16E opening in a diffuser 29 having a width at the angle α ranging between 12° and 30°, and a length L4 of 10 mm. The tooth have a deeps of 1.2 mm and a pitch of 1.5 mm; the
25 tested fluid was a polyurethane mixture comprising a polyol, an isocyanate and CO₂ dissolved at 4.7% on the total mass.

The polyol-isocyanate mixture had a density of 1050 Kg/m³
30 and a viscosity of 0.05Ns/m² while CO₂ had a density of 1.78 Kg/m³ and a viscosity of 1.37*10⁻⁵ Ns/m²; the output was of 235 l/min and the average rate in the slot, of the mixture, was of 6.50 m/s.

35 Along to the toothed portion 16D, as shown in figure 11, a

degree of degasification and concentration of CO₂ was noted in the whirling zone 30A, 30B and 31A, 31B, depending on Reynolds number; at the same time, changing the angle width of the diffuser 29 between 12° and 30° it was noted that
5 the detachment of the fluid threads occurred for angles of 18°-22°, or above.

The computer simulation proved the good nucleation effect of the toothed portion of the pressure drop slot 16, and
10 releasing of CO₂ for starting frothing of polyurethane mixture; computer simulation proved also goods results with small angle width of the diffuser 29.

From what has been said and shown it will be clear that a
15 process and a foam dispensing device have been provided for a polyurethane mixture which is pre-expanded or frothed by CO₂ dissolved under pressure, particularly for the production of expanded polyurethane foams of both flexible and rigid type, for example by means of apparatus or
20 systems of the continuous type. Nevertheless other possible applications of the process and of the device according to the present invention are not excluded.

CLAIMS

1. A process for the production of polyurethane foams comprising the steps of:

- 5 - mixing at least a first and a second chemically reactive components (A, B), such as a polyol and an isocyanate with carbon dioxide (CO₂) under critical pressure condition to maintain the carbon dioxide dissolved into the resulting liquid mixture;
- 10 - gradually reducing the pressure into the mixture while it is flowing at laminar condition along a first portion of a restricted flow path (16; 24) comprising a pressure-drop slot (16A; 24A) longitudinally extending in the flow direction and dimensioned to provide a back-pressure in
- 15 the upstream mixture sufficient to maintain the carbon dioxide in a dissolved state,

characterised by the addition step of:

- causing nucleation and frothing of the mixture, by generation localised turbulency and eddies formation to
- 20 release gaseous carbon dioxide into the mixture while it is flowing along a remaining portion (16B, 16C; 16D; 16E; 24B, 24C) of the restricted flow-path (16; 24) consisting of an extension of the pressure-drop slot (16A; 24A).

25 2. Process according to claim 1, wherein the localised turbulency and eddies formation in the liquid mixture is generated by abrupt angular diversions (16B, 16C; 16D; 16E; 24B, 24C) of the mixture flowing in the remaining portion (16B, 16C; 16D; 24B, 24C) of said flow path.

30 3. Process according to claim 1, wherein localised turbulency and eddies formation in the mixture is generated by successive abrupt changes (16B, 16C; 16E) in the direction of the flowing mixture, along the remaining flow

35 path.

4. Process according to claim 1, wherein localised
turbulency, nucleation and frothing, are generated by at
least one diversion of the flowing mixture close to the
5 exit of the remaining portion (16') of the flow path (16).

5. Process according to claim 2, wherein the sharp
angular diversions of the flow, are between 60° and 120°.

10 6. Process according to claim 5, in which the angle of
diversions of the flow are preferably between 60° and 105°.

7. Process according to claim 1, wherein the localised
turbulency conditions, are generated by causing the mixture
15 to flow along a Z-shaped portion (16E) of the remaining
flow path.

8. Process according to claim 1, wherein the localised
turbulency conditions are generated by flowing the mixture
20 along a remaining portion (16D) of the flow path (16)
provided with toothed side walls (17, 18).

9. Process according to claim 1, wherein the pressure
drop in the remaining portion (16b, 16C; 16D; 16E) of the
25 flow path (16) is comprised between 0.02 and 1 bar.

10. Process according to claim 9, wherein said
pressure drop is preferably between 0.1 and 0.5 bar.

30 11. Process according to claim 1, characterised by the
step of dividing the flow of the mixture into a plurality
of single flows along said first portion (16A, 24A) of the
flow path (16, 24).

35 12. Process according to claim 1, wherein localised

turbulency and frothing are generated by making the mixture to flow along a remaining portion (16B, 16C) of the flow path having increasing heights.

5 13. Device for dispensing a frothed polyurethane material, in the production of polyurethane foams, the device comprising:

 a distribution chamber (15, 22) for CO₂ containing
10 polyurethane foaming mixture, opening into a pressure drop zone (16) of a restricted flow path which extends in the direction of the flow, characterised in that said flow path (16) comprises a first portion (16A; 24A) provided by a pressure drop slot to gradually reduce the pressure in the flow of the mixture, and a second frothing portion (16B;
15 16D; 16E; 24B) consisting of an extension of the first portion of the flow path, conformed to cause angular diversions in the flowing mixture, downstream the pressure-drop slot (16A; 24A).

20 14. Device according to claim 13, wherein the angular diversion of the flow is between 60° and 120°, preferably between 60° and 105°.

 15. Device according to claim 13, wherein said second
25 portion (16E) is defined by a Z-shaped flow path.

 16. Device according to claim 13, wherein the axial
30 length of the second portion (16B; 16D; 16E; 24B) between adjacent diversions of the flow, is between 1 and 4 times the minimum height of the same flow path.

 17. Device according to claim 13, wherein said second portion (16D; 16E) of the flow path is provided with toothed side walls (17, 18).

18. Device according to claim 17, wherein the teeth (17) on one side wall are opposite to the teeth (18) on the other side wall.

5 19. Device according to claim 17, wherein the teeth (17) on one side wall are staggered in relation to the teeth (18) on the other side wall.

10 20. Device according to claim 17, wherein the number of the teeth (17, 18) on each side wall is between 1 and 5.

21. Device according to claim 17, wherein the teeth (17, 18) have a cross sectional triangular shape.

15 22. Device according to claim 21, wherein the angle width of the teeth (17, 18) is between 60° and 120°, preferably between 60° and 105°.

20 23. Device according to claim 21, wherein the pitch between the teeth (17, 18) is between 1 and 4 times the minimum height of the flow path.

24. Device according to claim 13, wherein said pressure-drop slot (16A) of the flow path (16) has a linear cross-sectional shape.

25 25. Device according to claim 13, wherein said pressure drop slot (24A) of the flow path (24) has a circular cross-sectional shape.

30 26. Device according to claim 12, wherein said slot (16A, 24A) is provided with continuous smooth side walls.

27. Device according to claim 13, wherein said first portion (16A, 24A) of the flow path, comprises a plurality

of axially extending holes.

28. Apparatus for the production of foamed polyurethane material from reactive chemical components comprising a polyol and an isocyanate which are mixed with CO₂ at a sufficient pressure for maintaining the CO₂ dissolved in a resultant liquid mixture, said apparatus comprising:

- a mixer device (14);
- a foamed material dispensing device (10), connected to the mixer device (14);

said dispensing device (10) including a distribution chamber (15; 22) for the liquid mixture opening into a flow path (16; 24) which extends in the direction of the flow,

wherein said flow path (16; 24) comprises a first portion (16A, 24A) in the form of an elongated pressure-drop slot, for gradual reduction of the pressure, and a second portion (16B, 24B) conformed to cause whirling or eddies formation into the flowing mixture by angular diversions of the flow, and a diffuser connected to the exit side of the flow path (16, 24).

29. Apparatus according to claim 28, wherein the diffuser is provided with an angular width designed to prevent detachment of the fluid threads from the diffuser side walls.
